Short running title: Enhanced O₂ availability in bioartificial pancreas

Abstract

The bio-artificial pancreas encapsulating pancreatic islets in immuno-protective hydrogel is a promising therapy for type 1 diabetes. As pancreatic islets are highly metabolically active and exquisitely sensitive to hypoxia, maintaining O₂ supply after transplantation remains a major challenge. In this study, we address the O₂ limitation by combining silicone-encapsulated CaO₂ (silicone-CaO₂) to generate O₂ with an extracellular hemoglobin O₂-carrier co-encapsulated with islets. We showed that the hemoglobin improved by 37 % the O₂-diffusivity through an alginate hydrogel and displayed anti-oxidant properties neutralizing deleterious reactive O₂ species produced by silicone-CaO₂. While the hemoglobin alone failed to maintain alginate macro-encapsulated neonate pig islets under hypoxia, silicone-CaO₂ alone or combined to the hemoglobin restored islet viability and insulin secretion, and prevented pro-inflammatory metabolism (PTGS2 expression). Interestingly, the combination took the advantages of the two individual strategies, improved neonate pig islet viability and insulin secretion in normoxia, and VEGF secretion and PDK1 normalization in hypoxia. Moreover, we confirmed the specific benefits of the combination compared to silicone-CaO₂ alone on murine pseudo-islet viability in normoxia and hypoxia. For the first time, our results show the interest of combining an O₂ provider with hemoglobin as an effective strategy to overcome O₂ limitations in tissue engineering.

Graphical Abstract

The bio-artificial pancreas encapsulating pancreatic islets in immuno-protective hydrogel is a promising therapy for type 1 diabetes. As pancreatic islets are highly metabolically active and exquisitely sensitive to hypoxia, maintaining O₂ supply after transplantation remains a major challenge.

Extracellular hemoglobin, Oxygen supply, Type 1 diabetes, Pancreatic islet, Bio-artificial pancreas, Tissue engineering

Introduction

Allotransplantation of human pancreatic islets is a necessary complement to insulin therapy for patients suffering from unstable type 1 diabetes (T1D). Over the past ten years, pancreatic islet graft in the liver portal vein has been shown to achieve 44% insulin independence 1 year after transplantation (Shapiro, 2006; Lablanche, 2015). However, the shortage of human donor organs and the need for lifelong immunosuppressive treatment to prevent the rejection of transplanted islets limit extension of this approach to a larger T1D patient population (Okere, 2016). The development of a bio-artificial pancreas (BAP) based on encapsulated pancreatic islets has been of growing interest to overcome the main hurdles to pancreatic islet transplantation. Encapsulation of islets in alginate hydrogel has been extensively studied in

order to prevent instant blood-mediated inflammatory reaction (IBMIR, a major cause of loss of islets grafted in the liver) (Naziruddin, 2014) and could prevent systemic immunosuppressive treatments that have to be used (Ludwig, 2013 & 2017, Dufrane, 2010).

Today, xenotransplantation of pig pancreatic islets remains the most promising complement to allotransplantation in order to address donor organ shortage. Pigs (*Sus scrofa domesticus*) are an almost unlimited and manageable source of islets with stable function and differentiated status. In particular, neonate pig islets (NPIs) can be isolated easily with high yields (Ricordi, 1990; Korbitt, 1996). Alginate micro-encapsulated NPIs transplantation in the peritoneal cavity has been successfully evaluated in clinical trials for unstable human T1D, with a significant reduction in the incidence of severe complications (Elliott, 2011; Valdes-Gonzalez, 2010). Unlike micro-encapsulation, transplantation of islets macro-encapsulated in a single larger device allows for easier monitoring, removal and replacement of the BAP with minimal risk. Alginate macro-encapsulated human islets were proven to be functional when grafted subcutaneously in humans for several months (Ludwig, 2013).

Transplantation of a BAP based on macro-encapsulated pig islets seems to be a promising alternative for overcoming the main hurdle to pancreatic islet transplantation. However, one of the main critical microenvironment parameter that limits the BAP efficacy is an insufficient O₂ supply to the encapsulated cells after transplantation (Dulong, 2007; Komatsu, 2017). Indeed, O₂ is only provided by passive diffusion through the immuno-protective capsule, while a high density of islets consuming a large amount of O₂ is required to reach therapeutic efficiency with implantable device size (Barkai, 2016). Furthermore, partial O₂ pressure (pO₂) in extravascular transplantation sites, including the subcutaneous space, is generally low (around 10 mmHg, 1% O₂) compared to the pancreas (40 mmHg) (Carlsson, 2001; Menger, 1989; Jansson L., 2002). This lack of O₂ is critical during the period preceding the neovascularization around the capsules, which occurs approximately 1 to 2 weeks post-transplantation (Jansson, 2002; Jones, 2007; Morini, 2007). Low O₂ tension has been shown to induce hypoxia-related oxidative stress (Rodriguez-Brotons, 2016 (a)) and metabolic changes

(Sato, 2011 & 2014) in islets resulting in insulin secretion impairment (Dionne, 1993), pro-inflammatory factor secretion (Brandhorst, 2016), and finally islet cell death (De Groot, 2003; Sato, 2014). In these conditions, designing a BAP without adequate O₂ supply is likely to lead to long-term graft failure and therapeutic inefficiency.

Extensive efforts have been made to enhance O₂ supply to encapsulated islets. The gas delivery is the most advanced technique, but requires multiple daily O₂-gas injections (Ludwig, 2012; Barkai, 2013). However the efficiency of this system is limited by the low O₂ diffusivity in the large clinically relevant device (Carlsson, 2018). Chemical O₂-generating biomaterials such as solid calcium peroxide (CaO₂) are promising to store large quantities of O₂ in an aqueous medium. Pedraza *et al.* (2012) designed a polymethyldisulfohexane-CaO₂ device (10 mm diameter, 1 mm height) able to release O₂ for 3 weeks. This device was shown to prevent the apparition of necrotic cores of adult porcine islets cultured in normoxia (McQuilling, 2017) and the hypoxia damage of murine MIN6 beta cells (Pedraza, 2012; Forget, 2017), rat pancreatic islets (Pedraza, 2012) and NPIs (Lee, 2017) for few days. However, according to Pedraza *et al.* (2012), the use of this device in 3D-construct leads to O₂ gradients and inhomogeneous distribution throughout the BAP. Moreover, such O₂-generating device could produce deleterious reactive oxygen species (ROS) such as hydrogen peroxide (H₂O₂) (Camci-Unal, 2013; Forget, 2017; McQuilling, 2017). O₂-carriers, such as hemoglobin, can store and release O₂ according to the pericellular environment pO₂ (Khattak, 2007; Le Pape, 2017 (a); Avila, 2006). By increasing O₂ saturating concentration, hemoglobin could increase the driving force and the transfer rate of O₂ through the encapsulating material (Schrezenmeir, 2001; Le Pape, 2017 (b)). Human hemoglobin is not stable in the extracellular environment and has been shown to induce oxidative stress when used as O₂-carrier or blood substitute (Alayash, 2014). More recently, native extracellular hemoglobin from the arenicole marine worm (*Arenicola marina*) (HEMOXCell, Hemarina, Morlaix, France) has been described to bind 156 O₂ molecules per hemoglobin molecule and to release O₂ through a sigmoid response according to cellular O₂ requirements (Le Pape, 2015). The main limitation of O₂-carriers

remains the low amount of O₂ stored compared to islet consumption. Rapidly the islets deplete this reservoir if an exogenous O₂ supply is not provided.

In the present study, we evaluated the pertinence of a combination of an O₂-carrier and an O₂-generating biomaterial, which could better prevent hypoxia in islet engineering devices. We first assessed the anti-oxidant properties of the extracellular HEMOXCell hemoglobin and its effect on O₂ diffusivity in alginate hydrogel. The biocompatible O₂-generating silicone-encapsulated calcium peroxide device (silicone-CaO₂), the O₂-carrier HEMOXCell hemoglobin and the combination of both were then evaluated for their ability to prevent hypoxia-induced damage to alginate macro-encapsulated NPIs.

Material and Methods

Islet isolation and encapsulation. Pig experiments were approved by the Pays de la Loire Ethics Committee (Approval 01074.01/02) and were carried out in compliance with the relevant European regulation guidelines (Directive 2010/63/EU). Neonate pig islets (NPIs) were isolated from the pancreas of 5- to 15-day-old Yucatan pigs (INRA PEGASE, Rennes, France) as described previously by Korbitt *et al.* (1996). NPIs were cultured in Ham's F10 (Dutscher, Brumath, France) supplemented with 10 mM glucose, 50 mM IBMX, 2 mM L-glutamine, 10 mM nicotinamide, 100 IU/ml penicillin and 100 mg/ml streptomycin and 0.5 % BSA (w/v) (NPIs culture medium). NPIs were quantified using the canonical standardized Islets Equivalent Quantities (IEQ, Ricordi, 1990). Clinical grade low viscosity and high guluronate sodium alginate 2.2% (w/v) (PRONOVA UP LVG, Novamatrix, Sandvika, United Kingdom) was used for islet encapsulation. Following a 24 h culture in normoxia (37 °C, 20% O₂, 5% CO₂), NPIs were gently mixed in the alginate (2500 IEQ/ml), and alginate macro-beads, 3 mm in diameter, were produced by extrusion through a 23 G needle using a syringe driver, into a 100 mM CaCl₂ gelation bath for 5 minutes. The alginate beads were cultured in NPI culture medium supplemented with 10% porcine serum (instead of BSA).

Oxygen supplier and carrier. The O₂-generating biomaterial was prepared by mixing calcium peroxide (Sigma-Aldrich) in polydimethylsiloxane (silicone, Sylgard® 184, Sigma-Aldrich) in a ratio 1:3 (weight/weight) as described by Pedraza *et al* (2012). A volume of 100 µL per well of silicone-CaO₂ was degassed and cross-linked in 48-well plates during 24 h at 60 °C. HEMOXCell hemoglobin (Hemarina, Morlaix, France) was mixed with the alginate before cross-linking into alginate macro-beads. In accordance with the literature (Rodriguez-Brotons, 2016; Le Pape, 2017a and 2017b), we screened concentrations of 50, 125 and 250 µg/mL of HEMOXCell on their ability to increase O₂ diffusivity.

Experimental design. To assess our oxygenation strategy, eight alginate beads containing NPIs (2500 IEQ/ml alginate) with or without 250 µg/mL HEMOXCell were cultured in 500 µL of culture medium, with or without the silicone-CaO₂ disk (Sup. Figure 1). Alginate-encapsulated NPIs were cultured at 37°C - 5% CO₂ either in a normoxia (145.7 mmHg O₂) or in a hypoxia chamber (STEMCELL Technologies Grenoble, France) filled with a 1% O₂ atmosphere (10 mmHg, Messer, Nantes, France) mimicking O₂ tension in the BAP after extravascular transplantation (Carlsson, 2001). NPI analysis and culture medium renewal were done after 2, 5 and 7 days. Normoxic (Ct-N) and hypoxic (Ct-H) controls correspond to alginate-encapsulated NPIs cultured without HEMOXCell nor silicone-CaO₂.

Islet viability assessment. NPI viability was qualitatively assessed by staining and imaging with ethidium bromide (red dead cells) and calcein AM (green viable cells) (Live&Dead, Life Technologies, Saint Aubin, France). Necrotic cell death was evaluated by quantifying lactate dehydrogenase activity (Absorbance unit (AU), LDH, Roche, Meylan, France) in culture supernatants. NPI intra-cellular ATP content (Relative light unit (RLU)) was determined using the CellTiter-Glo® 3D Cell Viability assay (Promega, Charbonnières-les-Bains, France). DNA content of encapsulated islets was assessed using the CyQuant Cell Proliferation Assay kit (Life Technologies). LDH absorbance, ATP luminescence and DNA fluorescence were measured on a FLUOstar OPTIMA luminometer (BMG Labtech, Champigny-sur-Marne, France).

This article is protected by copyright. All rights reserved.

Insulin secretion assay. Insulin secretion (ELISA quantification in supernatants, Mercodia, Upsala, Sweden) was evaluated by 30 min sequential incubations of alginate-encapsulated islets in basal medium (RPMI (PAA, Velizy-Villacoublay, France) with 2 mM L-glutamine, 0.5% BSA and 2.8 mM glucose), stimulation medium (basal medium supplemented with 20 mM glucose and 10 mM theophylline) and then basal medium again (Sup. Figure 2). Theophylline was used as insulin secretion potentiator as NPIs are immature islets (Korbitt, 1996). Insulin secretion stimulation indexes were insulin concentrations in supernatants with glucose/theophylline divided by basal level.

Transcriptomic analysis. NPIs were recovered from alginate beads by incubation for 20 min at 37°C in decapsulating solution (5 mM citrate and 1 mM EDTA in PBS). Total RNA (NucleoZOL, Macherey-Nagel, Düren, Germany) was reversely transcribed (MLV reverse transcriptase, Invitrogen, Waltham, MA, USA). RT qPCRs (CFX 96 Touch system (BioRad, Hercules, CA, USA) were performed with Hot FirePol EvaGreen mix (Solis Biodyne, Tartu, Estonia). RPL19 and PPIA gene expression were used to standardize target gene expression of PDK1 (Pyruvate dehydrogenase kinase 1), HO-1 (Heme oxygenase 1) and PTGS2 (Prostaglandin-endoperoxide synthase 2). Primers used for RT qPCR are listed in Table 1.

IL-6, MCP1 and VEGF quantification. Pro-inflammatory IL-6 (R&D systems, Lille, France) and MCP1 (Monocyte chemoattractant protein 1) secretion, and pro-angiogenic VEGF (vascular endothelial growth factor) secretion were assayed by ELISA in islet culture supernatants (Clinisciences, Nanterre, France).

Reactive oxygen species (ROS). Silicone-CaO₂ was incubated for 2, 5, 7 and 14 days in NPI culture medium, with or without HEMOXCell in normoxia. ROS in culture supernatants were quantified by chemiluminescence after addition of Horseradish peroxidase (8 U/ml, Sigma-Aldrich) and luminol (50 µM, Sigma-Aldrich) as described by Dahlgren *et al.* (2007). Luminescence was recorded immediately (FLUOstar OPTIMA). Hydrogen peroxide (Gifrer-Barbezat, Declines, France) was used as a standard.

Oxygen diffusivity in alginate hydrogel. The effect of HEMOXCell on oxygen transfer through the alginate hydrogel was assessed in a bioreactor. Alginate macro-beads supplemented or not with HEMOXCell were first deoxygenated in PBS (Eurobio, Courtaboeuf, France) supplemented with 1.8 mM CaCl_2 (PBS- Ca^{2+}) and stirred at 200 RPM in a hypoxic atmosphere (N_2). After reaching 0% O_2 , the deoxygenated PBS- Ca^{2+} solution was discarded and rapidly replaced by a previously air-saturated PBS- Ca^{2+} solution and stirred at 100 rpm. Dissolved oxygen concentrations in the PBS- Ca^{2+} solution were measured using a Clark type oxygen electrode (InPro 6850i, Mettler-Toledo, Viroflay, France) and Rhapsody software (Pierre Guerin Technologies, Niort, France).

Statistical analysis. Data are represented as the mean \pm SEM percentage of the normoxic control without HEMOXCell or silicone- CaO_2 (Ct-N). Minimums of 3 independent experiments were performed with biological duplicates. The significance of the differences between the groups was evaluated using a Mann-Whitney or paired Wilcoxon test with p value <0.05 considered as significant.

Results

O_2 diffusivity and reactive oxygen species (ROS). To assess the effect of HEMOXCell on O_2 transfer, the dissolved O_2 concentrations were measured in an initially air-saturated PBS- Ca^{2+} solution containing deoxygenated alginate beads with or without HEMOXCell (Figure 1A). O_2 transfer rate (Figure 1B) through the hydrogel was calculated as the initial slope of the dissolved O_2 quantities kinetics curves (dotted black lines on Figure 1A). O_2 transfer rate was significantly higher in the alginate beads containing 250 $\mu\text{g}/\text{mL}$ HEMOXCell than in the control alginate beads ($p < 0.05$, Figure 1B), while no improvement was achieved with 50 and 125 $\mu\text{g}/\text{mL}$ HEMOXCell (data not shown). The quantitative impact of oxygen transfer rate on O_2 diffusivity in the hydrogel was determined (Sup. data 1). Using the described model, it could be shown that addition of 250 $\mu\text{g}/\text{mL}$ HEMOXCell improved O_2 diffusivity in alginate

beads by 37% compared to the control. A concentration of 250 µg/mL HEMOXCell was thus chosen for the rest of the study.

Upon contact with water, encapsulated solid peroxide may produce cytotoxic reactive oxygen species such as H₂O₂. We thus quantified ROS in culture supernatants with silicone-CaO₂ ± 250 µg/mL HEMOXCell (Figure 1C). Silicone-CaO₂ produced high levels of ROS in supernatants from 58 ± 21 µmol/L after 2 days of culture, to 573 ± 115 µmol/L after 14 days (p<0.05, Figure 1C). However, HEMOXCell significantly reduced the presence of ROS produced by silicone-CaO₂ near to the limits of detection (p<0.05, Figure 1C).

Viability and function of encapsulated islets under normoxia. In order to assess the potential toxic side effects of our O₂ strategy on alginate-encapsulated pancreatic islets, NPIs were cultured for up to 7 days under unlimited O₂ supply, *i.e.* at low islet density and with an oxygen tension of 21% O₂ (Brandhorst D., 2016). Alginate-encapsulated NPIs in the presence of HEMOXCell or silicone-CaO₂ showed good overall viability throughout *in vitro* culture in normoxia according to Live&Dead staining (Sup. Figure 3A). In presence of HEMOXCell, encapsulated NPI metabolic activity was decreased on day 2 and increased on days 5 and 7 as objectified by the ATP content compared to the normoxic control (Ct-N, p<0.05, Figure 2A). On the other hand, silicone-CaO₂ alone induced a slight decrease in ATP content in alginate-encapsulated NPIs on day 7 compared to Ct-N (p<0.05, Figure 2A). Furthermore, the combination of both enhanced the ATP content of alginate-encapsulated NPIs compared to Ct-N (significant on day 7, p<0.05, Figure 2A). The combination also enhanced significantly NPI ATP contents comparatively to silicone-CaO₂ alone at days 5 and 7 (p<0.05, Figure 2A). Beside, an important deleterious effect of silicone-CaO₂ was observed on MIN6 pseudo-islets (MPIs) viability (Sup. Figure 4A). Indeed, a significant drop of ATP content was observed from 22 ± 6% on day 1 and up to 37 ± 8% after 6 days. As expected, the addition of HEMOXCell prevented the deleterious effect of silicone-CaO₂ on MPI viability as ATP content was not significantly different from Ct-N on days 1 and 6, and even increased on day 3

($p < 0.01$). Moreover, MPI ATP content was significantly increased by the combination compared to silicone-CaO₂ alone on days 3 and 6 ($p < 0.05$).

HEMOXCell seemed to induce a slight increase in LDH released by NPIs compared to Ct-N on day 7 of culture ($p < 0.05$, Figure 2B). Silicone-CaO₂ significantly decreased the level of LDH release in the NPI culture supernatant throughout culture ($p < 0.001$ on day 2, $p < 0.0001$ on day 5 and $p < 0.05$ on day 7, Figure 2B). In the presence of the combination, LDH release increased over time to become significantly higher compared to Ct-N after 7 days' culture ($p < 0.05$, Figure 2B). Insulin secretion response assays following glucose and theophylline stimulation were performed on encapsulated NPIs (Sup. Figure 2). HEMOXCell alone displayed no effect on NPI function. On the other hand, silicone-CaO₂ alone significantly decreased the NPI insulin secretion index on 5 days' culture ($p < 0.0001$, Figure 2C). Interestingly, the combination of the hemoglobin and silicone-CaO₂ maintained NPI insulin secretion indexes similar to Ct-N and they were even significantly increased on 7 days' culture ($p < 0.05$, Figure 2C).

The effect of the proposed O₂ supply strategies was also assessed in normoxia on the islet oxidative stress response (HO-1), metabolic shift from an aerobic mitochondrial pathway to an anaerobic fermentation (PDK1, Kim, 2006) and pro-inflammatory responses (PTGS2, Rodriguez-Brotons, 2016 (a); Vivot, 2014). HEMOXCell alone did not significantly modify HO-1, PDK1 and PTGS2 mRNA expression in encapsulated NPIs compared to Ct-N (Figures 3A and 3B), except a slight decrease in PTGS2 mRNA level on day 5 ($p < 0.05$, Figure 3C). Silicone-CaO₂ combined or not with HEMOXCell seemed to induce an increase in HO-1 expression on days 5 and 7 of culture compared to Ct-N ($p < 0.05$, Figure 3A). The enhancement by silicone-CaO₂ of the quantities of transcript PDK1 at day 2 (though not significant, Figure 3B) and PTGS2 at all time points studied (significant on day 7 compared to Ct-N, $p < 0.01$, Figure 3C) seemed to be reversed by the addition of HEMOXCell, excepted for PTGS2 at day 2, which stayed higher than Ct-N ($p < 0.01$, Figure 3C).

Viability of encapsulated islets under low O₂ tension. The efficiency of the oxygenation strategy was tested on encapsulated NPIs cultured under low O₂ tension (1% O₂). According to Live&Dead staining, NPI viability seemed to be moderately affected by hypoxia as only few red-stained cells were detected in the hypoxic condition compared to normoxia (Sup. Figure 3B). However, the hypoxic environment significantly diminished the NPI's ATP and DNA contents on days 2 and 7 compared to Ct-N ($p < 0.05$, Figures 4A and 4B, respectively), while the LDH release and HO-1 expression were significantly enhanced respectively on day 7 ($p < 0.05$, Figure 4C) and on days 5 and 7 ($p < 0.01$, Figure 4D). NPIs in the presence of HEMOXCell alone displayed very similar trends to those of the hypoxic control (Ct-H). HEMOXCell did not prevent the effects of hypoxia on NPI ATP (Figure 4A) and DNA content (Figure 4B), LDH release (Figure 4C) and HO-1 expression (Figure 4D). Silicone-CaO₂ alone, or in combination with HEMOXCell, restored NPI ATP, DNA and LDH values close to Ct-N (Figures 4A, 4B and 4C) and even increased DNA content on day 7 ($p < 0.05$, Figures 4B). At day 5, the combination increased ATP content by $67 \pm 18\%$ compared to Ct-N ($p < 0.01$, Figure 4A). Silicone-CaO₂ \pm HEMOXCell seemed to reduce HO-1 expression levels on day 5 and 7, but did not restore its normoxic level of expression (Figure 4D).

Concerning pseudo-islets, MPI viability without O₂ strategy was significantly affected all along the culture duration with a drop up to $55 \pm 2\%$ of the ATP content compared to Ct-N ($p < 0.001$, Sup. Figure 4B). As observed with NPIs, HEMOXCell alone did not restore MPI ATP content, while silicone-CaO₂ alone successfully maintained ATP values similar to Ct-N. Interestingly, the combination provided significant higher ATP contents than silicone-CaO₂ alone on days 3 and 6 ($p < 0.05$, Sup. Figure 4B).

Function of encapsulated islets under low O₂ tension. Insulin secretion by the alginate-encapsulated islets was evaluated following glucose + theophylline stimulation on 2, 5 and 7 days of culture (Sup. Figure 2 and Figure 5). As shown in Figure 5A, low oxygen tension significantly impaired NPI functionality after 2 days' culture: insulin secretion stimulation indexes were 5.1 ± 0.9 in Ct-N and 2.7 ± 0.4 in the Ct-H ($p < 0.01$, Figure 5A). Besides, no

significant difference was observed between the normoxic and hypoxic conditions after 5 and 7 days of culture. Despite no O₂ limitation (Ct-N), the NPIs stimulation indexes were already significantly decreased from 5 days of culture suggesting the lack of O₂ is not solely responsible for reduced secretory function after 2 days' culture. Therefore, it would be interesting to functionalized alginate with molecules known to promote islet microenvironment such as molecules from extracellular matrix (Llacua, 2018). On day 2, HEMOXCell alone failed to restore the Ct-N stimulation indexes ($p < 0.001$, Figure 5B). Silicone-CaO₂ alone and its combination with HEMOXCell maintained the insulin stimulation indexes on day 2 compared to Ct-N (Figure 5B) and consistently enhanced it compared to Ct-H ($p < 0.002$).

Consistently, the hypoxic environment in the presence or the absence of HEMOXCell triggered increased PDK1 expression (only significant on day 7, $p < 0.01$, Figure 5C). Addition of the silicone-CaO₂ disk failed to prevent this increased PDK1 expression compared to Ct-N on day 5 and 7 ($p < 0.01$, Figure 5C). The combination significantly decreased PDK1 expression on day 2 compared to Ct-N ($p < 0.01$) and restored Ct-N expression level on days 5 and 7 (Figure 5C).

Pro-inflammatory and pro-angiogenic state of encapsulated islets under low O₂ tension.

To evaluate the effect of silicone-CaO₂ ± HEMOXCell on activation of the inflammatory pathway in pancreatic islets, we quantified the concentrations of IL-6 and MCP1 secreted in culture supernatant of NPIs (Figure 6A and 6B), as well as expression of the inflammatory marker PTGS2 (Figure 6C). Under low O₂ tension, IL-6 and MCP1 secretion by NPIs was significantly decreased by $22 \pm 11\%$ and $30 \pm 10\%$ respectively compared to Ct-N on day 2 ($p < 0.05$, Figures 6A and 6B). In the presence of HEMOXCell or silicone-CaO₂ alone, IL-6 and MCP1 secretion seemed very similar to the hypoxic and normoxic conditions at all time points tested. Nevertheless, the HEMOXCell and silicone-CaO₂ combination induced a decrease of $39 \pm 18\%$ in IL-6 secretion on day 7 ($p < 0.05$, Figure 6A). The combination also seemed to induce an increase in MCP1 secretion by NPIs on day 2 ($p < 0.05$), which subsequently dropped

below the Ct-N level on day 7 ($p < 0.05$, Figure 6B). The hypoxic environment, with or without HEMOXCell, increased expression of the inflammatory marker PTGS2 on day 5 and 7 of culture ($p < 0.05$, Figure 6C). This overexpression was completely inhibited in the presence of silicone-CaO₂, combined or not with HEMOXCell, as PTGS2 expression levels remained close to the normoxic values (Figure 6C).

We evaluated VEGF release by pancreatic islets in our experimental conditions (Figure 6D). Hypoxia clearly enhanced the VEGF produced per NPIs by $410 \pm 215\%$ ($p < 0.001$), $197 \pm 113\%$ ($p < 0.01$) and $424 \pm 298\%$ ($p < 0.05$) respectively after 2, 5 and 7 days of culture compared to Ct-N. HEMOXCell enhanced the VEGF produced per NPIs by $657 \pm 198\%$ ($p < 0.001$), $467 \pm 301\%$ ($p < 0.01$) and $677 \pm 471\%$ ($p < 0.01$), respectively on 2, 5 and 7 days compared to Ct-N. The addition of HEMOXCell seemed to potentiate the effect of hypoxia on VEGF secretion by pancreatic islets (Figure 6D and Sup. Figure 5). Silicone-CaO₂ decreased the level of VEGF secreted by islets cultured in the hypoxic environment. Interestingly, the combination of the hemoglobin with silicone-CaO₂ increased NPI VEGF secretion compared to Ct-N by $143 \pm 57\%$ ($p < 0.05$), $70 \pm 46\%$ ($p < 0.05$) and $65 \pm 71\%$ (ns), after 2, 5 and 7 days of culture respectively.

Discussion

In this study, we showed *in vitro*, that the combination of an O₂-carrier and an O₂-generating biomaterial provided an adequate O₂ supply to improve the function, the viability and the metabolism of encapsulated NPIs in a confined and hypoxic environment.

Of potential interest, we described that hypoxia did not induce increased IL-6 and MCP1 pro-inflammatory factor release by NPIs, unlike previous studies using rat (Rodriguez-Brotons, 2016 (a); De Groot, 2003), adult pig (Goto, 2010) and human (Hals, 2013; Brandhorst, 2016) pancreatic islets under hypoxia. This weak impact of hypoxia on IL-6 and MCP1 secretion by NPIs could be related to their immaturity and relative resistance to hypoxic damages (Emamaullee, 2006). Nevertheless, we showed that low oxygen tension significantly damages

NPI function, metabolism and viability from 2 to 7 days' culture. In keeping with the literature describing the impact of ischemia or hypoxia on human pancreatic islets (Moritz, 2002; Giuliani, 2005; Lai, 2009; Cantley, 2012; Brandhorst, 2016; Hals, 2013), our results suggest that the innovative oxygen supply strategy developed in the present study may also meet the challenges of hypoxia during allotransplantation of macro-encapsulated human pancreatic islets.

The benefit of HEMOXCell was underlined for sustaining naked islet viability in a confined and hypoxic environment for a short 24-hour period (600 IEQ/mL, 2% O₂) (Rodriguez-Brotons, 2016 (b)), while our results indicated that this hemoglobin failed to prevent islet hypoxia damage for several days. As shown by other studies (Le Pape, 2015, 2017 (a) and 2017 (b); Rodriguez-Brotons *et al.* (2016 (b))), this result can not be explained by a toxic effect of HEMOXCell on NPIs. Indeed, when O₂ tension was not limiting, HEMOXCell increased LDH release together with an increase of the NPI ATP content, suggesting an unchanged proportion of lysed cells. Although HEMOXCell binds covalently a large quantity of O₂ molecules (n=156) (Rousselot, 2006), so 1 g of hemoglobin carries 4.3 x 10⁻³ mole of O₂. It would be necessary to co-encapsulate 13 mg of hemoglobin per mL of alginate hydrogel to provide sufficient O₂ for 2500 IEQ of islets per mL of alginate cultured for 7 days in hypoxia. Relying only on the O₂ reservoir capacity of the molecule, the quantity of hemoglobin necessary is impracticable and does not make it possible to mitigate hypoxia for a long period in the absence of other O₂ supply. Nevertheless, we showed that addition of extracellular hemoglobin to the alginate hydrogel increased the O₂ transfer rate and diffusivity through the immunoprotective capsule. For the first time, we quantified that 250 µg/ml hemoglobin increased O₂ diffusivity through the hydrogel by 37%, supporting the fact that HEMOXCell alone in normoxia induces a slight increase in the viability of macro-encapsulated NPIs and MPIs. Thanks to this property, the presence of HEMOXCell in the BAP could alleviate the O₂ gradients in a macro-capsule and promote O₂ supply from an exogenous O₂ source or from vascularization around the BAP.

The silicone-CaO₂ disk provided enough O₂ to prevent an anaerobic metabolic shift and the death of islet cells induced by hypoxia for up to 7 days. Pedraza *et al.* (2012) highlighted that the effect of the PDMS-CaO₂ disk on the murine MIN6 cell line was only effective when O₂ concentration was limiting (high cell concentration and/or low O₂ tension), while a deleterious effect occurred in case of local excess in O₂. The importance to use this O₂-generating material only in situations where hypoxia is a concern was also proposed by McQuilling *et al.* (2017). Similarly, in our study, the benefit of silicone-CaO₂ in preventing hypoxia-induced islet damage was observed, while its addition in normoxic conditions may decrease ATP content and glucose-dependent insulin secretion, and seemed to increase islet oxidative stress, as shown by increased HO-1 expression. This could be linked to the high levels of ROS produced by one disk of silicone-CaO₂, as also described for the PDMS-CaO₂ disk (Coronel, 2017). Indeed, partial reduction of H₂O₂ produces free radicals, which cause oxidative stress. Lower or similar hydrogen peroxide concentrations than those recorded here induced persistent beta cell dysfunction after short or long-term exposure (Li, 2009; Maechler, 1999; Fu-Liang, 2006). Pancreatic beta cells are indeed sensitive to oxidative stress due to their low level of antioxidant enzyme expression (Tiedge, 1998; Lenzen, 1996).

Our study highlights the specific benefits of the O₂-carrier and the O₂-generator to overcome O₂ limitation in the BAP. The association of the hemoglobin and silicone-CaO₂ takes advantages from the two individual strategies, and shows combined effects to maintain the function, metabolism and viability of encapsulated islets in the BAP under low or high O₂ tension.

The addition of extracellular hemoglobin prevented the negative effects of the presence of silicone-CaO₂ under normoxia on NPI viability, function and oxidative stress. As an explanation, we showed that HEMOXCell can neutralize the ROS produced by silicone-CaO₂. This is consistent with previous studies describing a super-oxidase dismutase-like activity from HEMOXCell (Rousselot, 2006; Le Pape, 2015). HEMOXCell may also have a catalase-like activity leading to the conversion of H₂O₂ into O₂ and H₂O, as described for some others

hemoglobins (González-Sánchez, 2011). When used as oxygen-carrier or blood substitute, hemoglobins extracted from red blood cells have shown the main disadvantage of inducing oxidative stress and ROS production linked to hemoglobin degradation and heme toxicity (Eversea, 1997; Alayash, 2014). We described here that a naturally-occurring extracellular hemoglobin did not produce ROS in the islet culture conditions and did not induce over-expression of the oxidative stress marker HO-1 in NPIs. Therefore, the hemoglobin may reduce oxidative stress produced by O₂-generation via hydration of solid peroxides, and promote its integration in the BAP.

According to Pedraza *et al.* (2012), the main drawback of an O₂-generating biomaterial, such as silicone-CaO₂, within the BAP, is generation of detrimental O₂ gradients, resulting in both hypoxic and hyperoxic stress. In our study, the capacity of HEMOXCell to increase O₂ diffusivity in the alginate macrocapsule was demonstrated. This property could help to better buffer O₂ tension in the BAP supplied by the O₂-generating biomaterial or, in the long term, by vascularization around the BAP. However, the angiogenic potential of pancreatic islets is correlated to the decrease of O₂ tension (Vasir, 1998; Coronel, 2017), and overcoming the problem of hypoxia in the BAP could delay revascularization of the graft surface. Consistently, providing O₂ through the addition of silicone-CaO₂ reverts beneficial secretion of VEGF by NPIs cultured in a hypoxic environment. A specific increase in VEGF secretion in the presence of the hemoglobin under normoxia was also observed. This suggests that the hemoglobin may have a specific effect on pro-angiogenic pathway activation. Therefore, the presence of HEMOXCell could improve BAP engraftment by maintaining a beneficial pro-angiogenic signal without O₂ limitation.

Low oxygen tension has been shown to induce a pro-inflammatory state in pancreatic islets (Rodriguez-Brotons, 2016 (a); De Groot, 2003; Goto, 2010; Hals, 2013; Brandhorst, 2016)) which may lead to activation of an immune response toward the graft (Vivot, 2014). Rodriguez-Brotons (2016 (b)) showed that the hemoglobin significantly increased PTGS2 expression compared to a hypoxic control. In our conditions, no specific effect from

HEMOXCell alone on the expression of PTGS2 was observed. The combination of HEMOXCell with the silicone-CaO₂ disk even prevented the increased pro-inflammatory state of NPIs under low O₂ tension by decreasing hypoxia-induced PTGS2 over-expression. Therefore, correction of islet hypoxia in the BAP should decrease secretion of pro-inflammatory molecules by encapsulated islets and prevent activation of a deleterious hypoxia-mediated immune response. In addition to correction of islet hypoxia, improvements of islet microenvironment in the BAP should also be considered in order to enhance beta cell survival and function (Llacua, 2018).

This work provides compelling evidence that incorporation of HEMOXCell in alginate confers further advantages to the BAP. Firstly, the hemoglobin should overcome the obstacle of an *in vivo* use of silicone-CaO₂ by (i) neutralizing ROS produced by silicone-CaO₂, (ii) homogenizing oxygen concentration in the BAP by increasing its diffusivity from the oxygen provider to the pancreatic islets and (iii) favoring BAP surface neovascularization by increasing the release of pro-angiogenic VEGF. Finally, the increase in O₂ diffusivity with the extracellular hemoglobin could also make it possible to create a thicker BAP or to increase islet density in the BAP. To ensure physiological O₂ supply to pancreatic islets in the BAP, it will be necessary to design an oxygenation strategy meeting specific islet requirements by optimizing islet density, silicone-CaO₂ and hemoglobin concentrations in the BAP. This promising O₂-solution could also be used in other applications requiring enhanced O₂ supply such as islet isolation procedures, organ preservation, and in other tissue engineering devices or industrial bioprocesses.

Table**Table 1.** RT qPCR primer sequences

Target	Forward	Reverse
RPL19	AACTCCCGTCAGCAGATCC	AGTACCCTTCCGCTTACCG
PPIA	CACAAACGGTTCCCAGTTTT	TGTCCACAGTCAGCAATGGT
PDK1	CAGGACAGCCAATACAAGTGG T	GTGGACTTGAATAGGCGGGTA A
H01	GCTGACCCAGGACACTAAGG	GGAGAGGACGCTGAGCTG
PTGS 2	CTCTTCCTCCTGTGCCTGAT	TTTTTCCACAACCTTCCTTTGAA

Figures

Figure 1. O₂ diffusivity and reactive oxygen species (ROS). A: Dissolved O₂ quantities kinetics. Deoxygenated alginate beads containing or not containing HEMOXCell were placed in air-saturated PBS-Ca²⁺ solution in a stirred bioreactor. Dissolved O₂ concentrations were measured in the PBS-Ca²⁺ solution during the O₂ transfer assay. B: O₂ transfer rate in alginate beads (n=6). The O₂ transfer rates (nmol/min) were measured as the initial slope of the dissolved O₂ quantities kinetics curves during the first X minutes (dotted black lines, Figure 1A). *p<0.05 compared to the control (Wilcoxon). C: Reactive oxygen species (ROS) measured in NPI culture medium containing or not silicone-CaO₂ and/or HEMOXCell in normoxia (n=7). Control was NPI culture medium without silicone-CaO₂ or HEMOXCell. ROS production was assessed after 2, 5, 7 and 14 days in culture supernatants. *p<0.05 compared to the control (Wilcoxon).

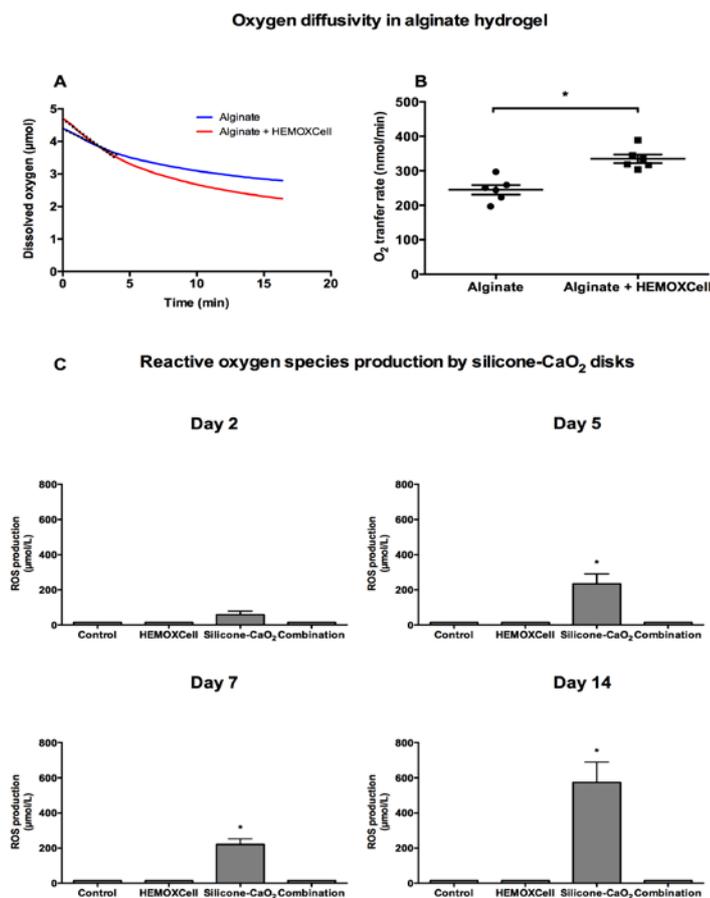

Figure 2. Viability and function of encapsulated islets under normoxia. NPIs (2500 IEQ/mL alginate) were cultured for 2, 5 and 7 days in normoxia with or without silicone-CaO₂ and/or HEMOXCell. A: intracellular ATP content in encapsulated islets (n=4-5). B: quantification of lactate dehydrogenase (LDH) released by encapsulated islets in culture supernatant (n=4-5). C: insulin secretion stimulation indexes of encapsulated islets calculated from glucose-stimulated insulin secretion assays (n=3-5). Results from independent experiments are expressed as mean percentage \pm SEM of the control without HEMOXCell nor silicone-CaO₂ (Ct-N) (horizontal lines). *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001 compared to Ct-N (Mann-Whitney).

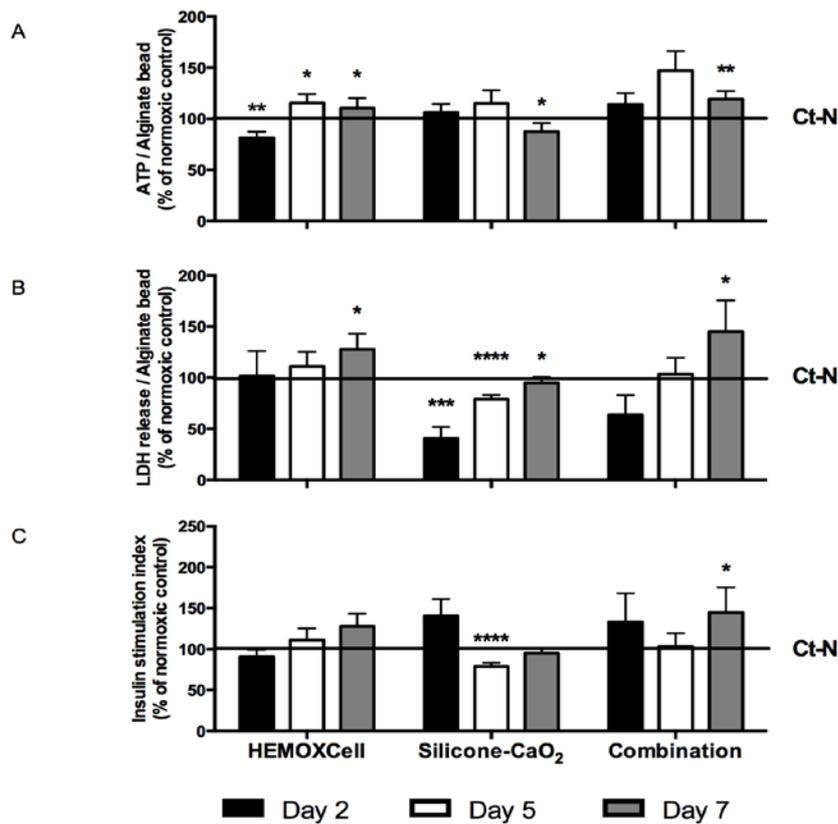

Figure 3. Metabolism of islets under normoxia. RT qPCR was performed on decapsulated NPIs after 2, 5 and 7 days' culture in a normoxic environment with or without HEMOXCell and silicone-CaO₂. A, B and C respectively represent expression of HO-1, PDK1 and PTGS2 in islets (n=3-6). Results from independent experiments are expressed as mean percentage \pm SEM of the control without HEMOXCell nor silicone-CaO₂ (Ct-N) (horizontal lines). *p<0.05, **p<0.01 compared to Ct-N (Mann-Whitney).

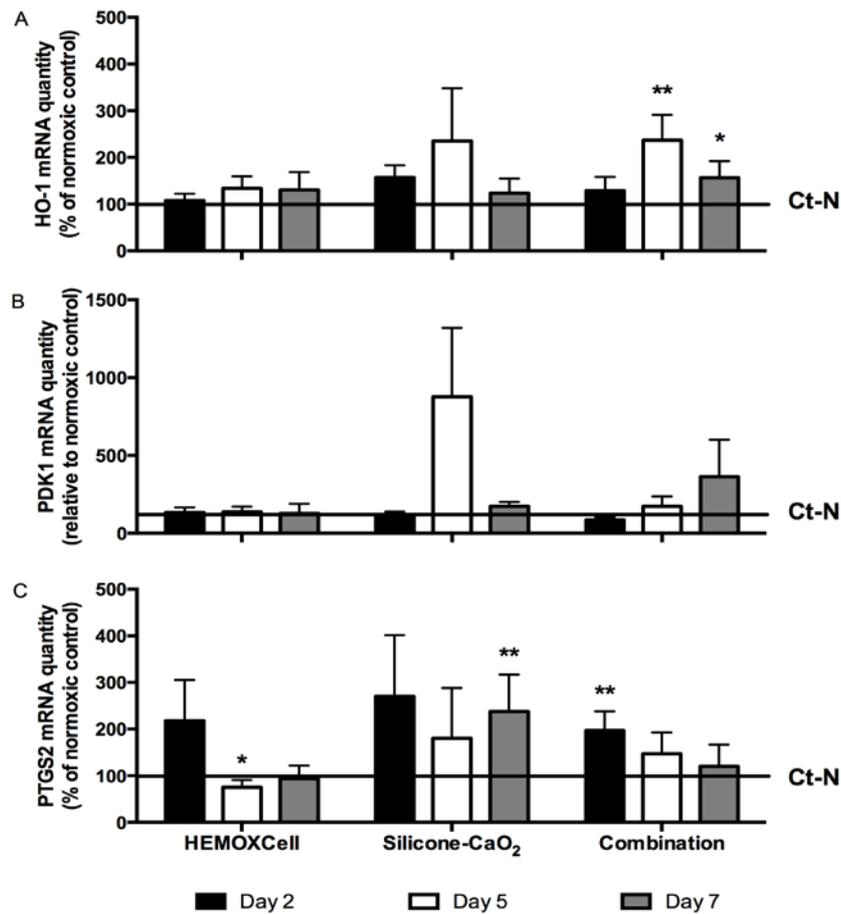

Figure 4. Viability of encapsulated islets under low O₂ tension. NPIs were cultured for 2, 5 and 7 days in hypoxic conditions with or without silicone-CaO₂ and/or HEMOXCell. A: intracellular ATP content in encapsulated islets representative of viable cell number (n=4-5). B: DNA content in encapsulated islets (n=6). C: cell lysis quantification in encapsulated islets by measuring lactate dehydrogenase (LDH) released in the culture supernatant (n=4-5). D: HO-1 mRNA expression in NPIs (n=3-6). Results from independent experiments are expressed as the mean percentage \pm SEM of the normoxic control without HEMOXCell nor silicone-CaO₂ (Ct-N) (horizontal lines). *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001 compared to Ct-N (Mann-Whitney).

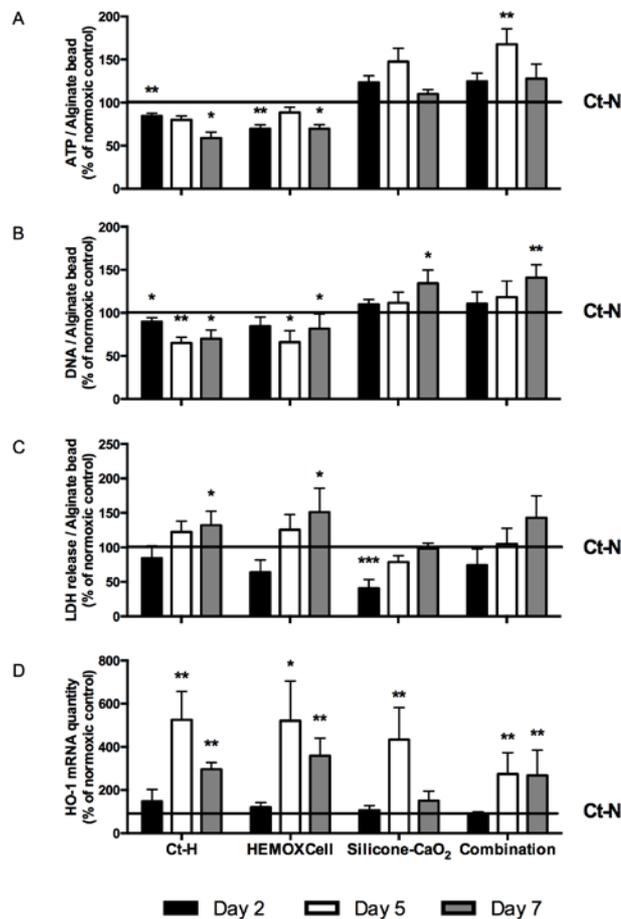

Figure 5. Function of encapsulated islets under low O₂ tension. NPIs were cultured for 2, 5 and 7 days. A: insulin secretion stimulation indexes calculated from glucose-stimulated insulin secretion assays for encapsulated NPIs cultured in a normoxic or hypoxic environment (n=4-5). Results from independent experiments are expressed as mean \pm SEM. **p<0.01 (Mann-Whitney). B: insulin secretion stimulation index calculated from glucose-stimulated insulin secretion assays on encapsulated NPIs cultured in the hypoxia chamber with or without silicone-CaO₂ and/or HEMOXCell (n=4-5). C: PDK1 mRNA expression in NPIs (n=4-5). For B and C, results from independent experiments are expressed as the mean percentage \pm SEM of the normoxic control without HEMOXCell nor silicone-CaO₂ (Ct-N) (horizontal lines). *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001 compared to Ct-N (Mann-Whitney).

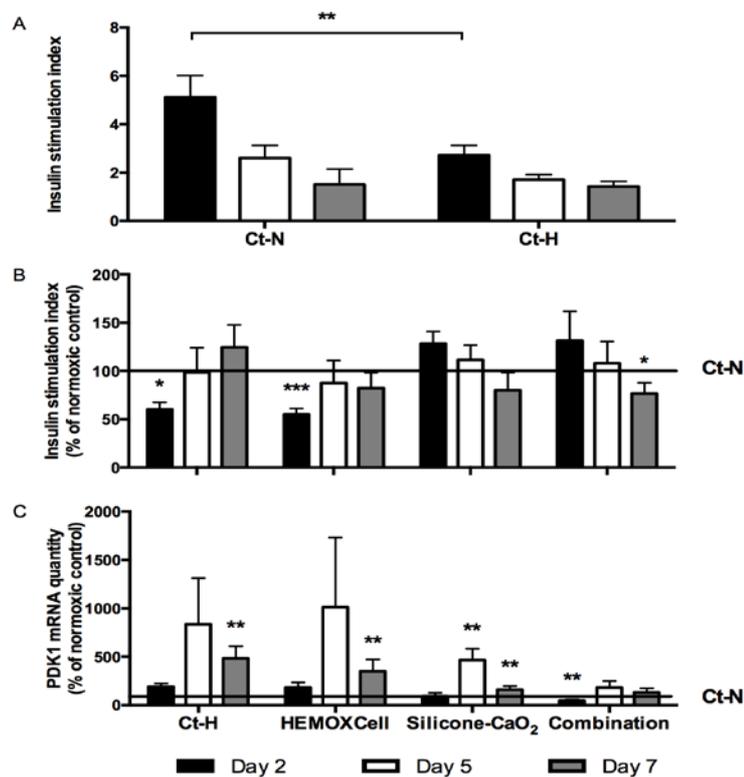

Figure 6. Pro-inflammatory and pro-angiogenic state of encapsulated islets under low O_2 tension. NPIs were cultured for 7 days in the hypoxia chamber with or without silicone- CaO_2 and HEMOXCell. Controls were alginate-encapsulated islets cultured in normoxic or hypoxic conditions without HEMOXCell nor silicone- CaO_2 (Ct-N et Ct-H). A, B and D respectively represent the production of IL-6, of MCP1 and VEGF by neonate pig islets (n=6). C: PTGS2 expression in NPIs (n=3-6). Results from independent experiments are expressed as the mean percentage \pm SEM of the normoxic control without HEMOXCell nor silicone- CaO_2 (Ct-N) (horizontal lines). * p <0.05, ** p <0.01, *** p <0.001 compared to Ct-N (Mann-Whitney).
